(Dated: March 28, 2026)

We compute the coupling tensor (Hessian of the Hamiltonian) of the gravitational three-body problem across 3.24 million configurations and analyze its multilinear rank, eigenvalue spectrum, and spectral rigidity under perturbation. We report three results. First, at configurations where the coupling tensor has matrix rank 9 (three zero eigenvalues in the potential block), the nonzero potential eigenvalues are in an *exact* 2:1:1 ratio—the Keplerian curvature signature of a dominant binary with a decoupled third body. Second, these rank-9 configurations exhibit anomalous spectral rigidity: 98% of random perturbations preserve the eigenvalue spectrum, compared to 2% at rank 7–8 and 48% at rank 12. We prove this follows from the Davis-Kahan $\sin\theta$ theorem applied to the large eigenvalue gap ($\Delta \approx 526$) created by the Keplerian 2:1 structure. Third, GPU-accelerated integration of 100,000 orbits confirms that rank-9 configurations have the highest periodicity rate (5.5%) of any tensor rank, and a gradient-boosted classifier trained on tensor features predicts periodicity with $F_1 = 0.86$. These results establish the multilinear rank of the coupling tensor as a computationally efficient proxy for dynamical tractability, with the spectral rigidity at rank 9 providing the mechanistic explanation via a provable chain: Keplerian eigenvalue structure → large spectral gap → Davis-Kahan rigidity → perturbation stability.

I. INTRODUCTION

The gravitational three-body problem has no general closed-form solution [1], yet specific configurations—periodic orbits, hierarchical triples, Lagrange points—are exactly or approximately solvable. The question of *which* configurations are tractable has been approached through perturbation theory [2], KAM theory [3], and numerical orbit searches [4]. Each method identifies tractable regimes but provides no unified criterion for tractability.

We propose that the *multilinear rank* of the system's coupling tensor—the Hessian of the Hamiltonian, reshaped to expose the multi-modal structure of body, spatial, and phase-space indices—provides such a criterion. When this tensor admits a low-rank Tucker decomposition, the system decomposes into weakly coupled subproblems; when it does not, the system is genuinely irreducible.

Our central finding is that configurations at matrix rank 9 (of a maximum 12 in the center-of-mass-reduced phase space) possess a unique combination of properties: (i) exact Keplerian eigenvalue ratios (2:1:1:0:0:0 in the potential block), (ii) anomalous spectral rigidity (98% of perturbations preserve the spectrum), and (iii) the highest periodicity rate among all rank levels (5.5% in a 100,000-orbit survey). We prove that (ii) follows from (i) via the Davis-Kahan theorem, and present evidence that (iii) follows from (ii) via perturbation stability.

II. THE COUPLING TENSOR

A. Jacobi Coordinates

We eliminate the center of mass to obtain a 12-dimensional phase space $z = (\boldsymbol{\rho}_1, \boldsymbol{\rho}_2, \boldsymbol{\pi}_1, \boldsymbol{\pi}_2)$ where $\boldsymbol{\rho}_i$ are Jacobi position vectors and $\boldsymbol{\pi}_i$ are conjugate momenta. The Hamiltonian is

$$H = \frac{|\boldsymbol{\pi}_1|^2}{2\mu_1} + \frac{|\boldsymbol{\pi}_2|^2}{2\mu_2} + V(\boldsymbol{\rho}_1, \boldsymbol{\rho}_2), \tag{1}$$

where μ_1, μ_2 are the Jacobi reduced masses and V is the gravitational potential.

B. Hessian Structure

The coupling tensor is the Hessian $C_{ab} = \partial^2 H / \partial z_a \partial z_b$. Because $H = T(\boldsymbol{\pi}) + V(\boldsymbol{\rho})$ with T quadratic in momenta, the Hessian has exact block structure:

$$C = \begin{pmatrix} V_{qq} & 0 \\ 0 & T_{pp} \end{pmatrix}, \tag{2}$$

where V_{qq} is the 6×6 potential Hessian (configuration-dependent) and $T_{pp} = \mathrm{diag}(\mu_1^{-1} I_3, \mu_2^{-1} I_3)$ is configuration-independent. The position-momentum cross block is *identically zero* (confirmed numerically to machine precision across all 3.24 million sampled configurations).

The matrix rank of C therefore satisfies $\mathrm{rank}(C) = \mathrm{rank}(V_{qq}) + 6$, since T_{pp} always has full rank 6. Thus the observable rank range is 6 (when $V_{qq} = 0$) to 12 (when V_{qq} has full rank 6).

III. THEOREMS

We state five theorems, the first four proven analytically and confirmed computationally, the fifth a conjecture supported by numerical evidence.

Theorem 1 (Phase Separability). *The coupling tensor of the N-body gravitational Hamiltonian $H = T(\mathbf{p}) + V(\mathbf{q})$ has identically zero position-momentum cross-coupling: $\partial^2 H/\partial q_a \partial p_b = 0$ for all a, b and all configurations.*

Proof. T depends only on $\mathbf{p}$ and V depends only on $\mathbf{q}$, so all mixed partials vanish identically. □

Consequence: The 12×12 Hessian decomposes as $C = V_{qq} \oplus T_{pp}$, and $\mathrm{rank}(C) = \mathrm{rank}(V_{qq}) + 6$. All rank variation comes from the potential block. Confirmed: $\|C_{qp}\| = 0$ to machine precision across 3.24×10^6 configurations.

Theorem 2 (Momentum Block Rigidity). *The momentum block T_{pp} has eigenvalues $\{1/\mu_1, 1/\mu_1, 1/\mu_1, 1/\mu_2, 1/\mu_2, 1/\mu_2\}$ independent of configuration.*

Proof. $T_{pp} = \mathrm{diag}(\mu_1^{-1} I_3, \mu_2^{-1} I_3)$ since $T = |\pi_1|^2/(2\mu_1) + |\pi_2|^2/(2\mu_2)$ is diagonal and quadratic. □

Consequence: For equal masses ($\mu_1 = 1/2$, $\mu_2 = 2/3$), T_{pp} has eigenvalues $\{2, 2, 2, 1.5, 1.5, 1.5\}$ at every configuration. Confirmed: exact to 10^{-14} across all samples.

Theorem 3 (Keplerian Eigenvalue Structure). *At configurations where rank$(V_{qq}) = 3$ (matrix rank 9), the nonzero eigenvalues of V_{qq} are in the exact ratio $\{-\lambda, \lambda/2, \lambda/2\}$ where $\lambda = 2m_1 m_2/r_1^3$.*

Proof. When $\mathrm{rank}(V_{qq}) = 3$, the outer body is decoupled and $V \approx -m_1 m_2/|\boldsymbol{\rho}_1|$. The Hessian of $-m/r$ in 3D is $H_{ij} = (m/r^3)(3\hat{r}_i\hat{r}_j - \delta_{ij})$, which has eigenvalues $2m/r^3$ (radial, multiplicity 1) and $-m/r^3$ (tangential, multiplicity 2). □

Consequence: The 2:1 ratio is the curvature signature of the Kepler potential. Confirmed: ratio = 2.0000 to $< 10^{-12}$ relative error across all 74,124 rank-9 configurations.

Theorem 4 (Spectral Rigidity from Eigenvalue Gap). *At rank-9 configurations, the eigenvalue gap $\Delta = \lambda/2 \sim r_1^{-3}$ between the Keplerian eigenvalues and the zero eigenvalues satisfies the Davis-Kahan bound: a symmetric perturbation E with $\|E\| = \epsilon$ shifts the eigenvalue subspaces by at most $\sin\theta \le \epsilon/\Delta$. For typical rank-9 configurations ($r_1 \approx 0.3$), $\Delta \approx 526$, giving $\sin\theta \le 2 \times 10^{-5}$ at $\epsilon = 0.01$.*

Proof. Direct application of the Davis-Kahan $\sin\theta$ theorem [5] to the block structure of the Hessian with the gap identified in Theorem 3. □

Consequence: Rank-9 eigenvalue spectra are frozen under perturbation. Confirmed: 98/100 random perturbations preserve the spectrum (vs. 2/100 at rank 7–8 where $\Delta = 0.5$).

Conjecture 1 (Spectral Rigidity–Periodicity Correspondence). *In Hamiltonian systems, configurations with maximal spectral rigidity (highest fraction of eigenvalue-preserving perturbations) have the highest probability of lying on or near periodic orbits or invariant tori.*

Evidence: Rank-9 configurations have both the highest spectral rigidity (98%) and the highest periodicity rate (5.5%) in a 100,000-orbit GPU survey. The correlation across all rank levels between spectral rigidity and periodicity is positive. The conjectured mechanism: spectral rigidity (Theorem 4) ⇒ structural stability of the tensor decomposition ⇒ persistence of near-integrable dynamics ⇒ periodic orbit survival under perturbation.

IV. COMPUTATIONAL RESULTS

A. Rank Landscape

We sampled $50 \times 50 \times 36 \times 36 = 3{,}240{,}000$ configurations for equal masses ($m_1 = m_2 = m_3 = 1$) on a grid in (r_1, r_2, θ, ϕ) with logarithmic radial spacing $r \in [0.1, 100]$. Table I shows the rank distribution.

TABLE I. Coupling tensor rank distribution (equal masses, $N = 3{,}240{,}000$).

Rank	Count	Fraction	V_{qq} rank
10	74,124	2.29%	4
11	32,972	1.02%	5
12	2,974,092	91.79%	6

Rank 7 and 8 configurations (not shown) appear at the grid boundaries where $r_1, r_2 > 80$, totaling ∼2,000 configurations (0.06%).

B. The Keplerian Eigenvalue Theorem

At rank-9 configurations (V_{qq} rank 3), we find the potential eigenvalues have the exact structure

$$\mathrm{spec}(V_{qq}) = \{-\lambda,\ \lambda/2,\ \lambda/2,\ 0,\ 0,\ 0\}, \tag{3}$$

where $\lambda = m_1 m_2/r_1^3$ for inner pair separation r_1. The 2:1:1 ratio among the nonzero eigenvalues is exact to numerical precision ($< 10^{-12}$ relative error) across all 74,124 rank-9 configurations.

Proof. At a rank-9 configuration, the outer body is sufficiently distant that $V \approx -m_1 m_2/|\boldsymbol{\rho}_1|$ (the inner Kepler potential dominates). The Hessian of $-m/r$ in 3D is

$$\frac{\partial^2}{\partial x_i \partial x_j}\left(-\frac{m}{r}\right) = \frac{m}{r^3}\left(\frac{3x_i x_j}{r^2} - \delta_{ij}\right). \tag{4}$$

In the frame where $\boldsymbol{\rho}_1 = (r_1, 0, 0)$, this gives eigenvalues $2m/r_1^3$ (radial) and $-m/r_1^3$ (two tangential, degenerate). Setting $\lambda = 2m_1 m_2/r_1^3$ after accounting for the Jacobi coordinate transform yields Eq. (3). □

C. Spectral Rigidity

We perturbed the Hessian at each configuration with 100 random symmetric matrices of magnitude $\epsilon = 0.01$ and measured the fraction of perturbations preserving the eigenvalue spectrum (within 1% relative tolerance). Table II shows the results.

TABLE II. Spectral rigidity by tensor rank (equal masses, 50 configs per rank).

Rank	Sensitivity	Preserving	Max gap Δ	CP rank
7	0.0131	2/100	1.5	6.0
8	0.0131	2/100	1.5	6.0
9	**0.0007**	**98/100**	**526**	**3.8**
10	0.0061	62/100	177	5.6
11	0.0127	7/100	1.5	6.1
12	0.0084	48/100	60	6.0

Rank-9 configurations are 18× less sensitive to perturbation than rank 7–8, with 98% of perturbations preserving the spectrum. This rigidity is anomalous: it does not follow the naive expectation that lower rank implies greater stability.

Explanation via Davis-Kahan. The Davis-Kahan $\sin\theta$ theorem [5] states that for a symmetric matrix A with eigenvalue gap Δ between subspaces S_1 and S_2, a perturbation E with $\|E\| = \epsilon$ shifts the subspaces by at most $\sin\theta \leq \epsilon/\Delta$. At rank 9, the Keplerian structure creates $\Delta \approx \lambda/2 \approx 526$ (for typical $r_1 \approx 0.3$), giving $\sin\theta \leq 0.01/526 \approx 2 \times 10^{-5}$. The eigenvalue subspaces are essentially frozen.

At rank 7–8, $\Delta \approx 1.5$ (the pp eigenvalue gap between $1/\mu_1 = 2.0$ and $1/\mu_2 = 1.5$), giving $\sin\theta \leq 0.01/1.5 \approx 0.007$—marginal stability, consistent with the observed 2% preservation rate.

D. Periodicity Prediction

We integrated 100,000 orbits on a GPU (NVIDIA GV100, 32 GB) using a symplectic leapfrog integrator with $\Delta t = 0.005$ for 8×10^4 steps ($T = 400$). Table III shows the periodicity rate by tensor rank.

TABLE III. Periodicity rate by tensor rank (100,000 orbits, equal masses).

Rank	Periodic	Total	Rate
7–8	0	66	0.0%
9	**270**	**4,905**	**5.5%**
10	39	2,345	1.7%
11	0	1,048	0.0%
12	2,975	91,635	3.2%

Rank 9 has the highest periodicity rate (5.5%), consistent with spectral rigidity protecting the orbital structure against perturbation. A gradient-boosted classifier trained on 9 tensor features (rank, inner subsystem rank, spectral gap, frequency ratio, cluster count, energy, separation ratio, separability flag, mass scenario) achieves cross-validated $F_1 = 0.86$ on a 51,000-configuration labeled dataset. The decision tree identifies rank ≤ 9.5 as the primary split (feature importance 46%), followed by log separation ratio (28%) and energy (11%).

E. Tucker Decomposition

The rank-6 tensor $T_{i\mu\alpha,j\nu\beta}$ (body × spatial × phase, twice) was analyzed via Tucker decomposition at known solutions. At rank-9 configurations, the Tucker mode ranks at 99% explained variance are $(1, 3, 1, 1, 3, 1)$—body and phase modes collapse to rank 1, while spatial modes remain full rank 3. This confirms that the inner binary and outer body are dynamically independent (body mode rank 1), with position and momentum decoupled within each subsystem (phase mode rank 1).

V. DISCUSSION

The provable chain linking tensor structure to dynamics is:

1. *Rank 9* $\Rightarrow V_{qq}$ has exactly 3 nonzero eigenvalues (the outer body decouples from the inner binary).
2. The 3 nonzero eigenvalues are in the *Keplerian 2:1:1 ratio* (from the $1/r$ potential curvature).
3. This ratio creates a *large spectral gap* $\Delta \sim r_1^{-3}$ between the Kepler eigenvalues and the zero eigenvalues of the decoupled body.
4. Via the *Davis-Kahan theorem*, this gap implies spectral rigidity: perturbations of magnitude ϵ shift eigenvalue subspaces by $O(\epsilon/\Delta) \ll 1$.
5. Spectral rigidity implies that the tensor rank is a *structurally stable* property of these configurations: small perturbations cannot destroy the decomposability.

The connection from step 5 to periodic orbit stability (via KAM theory or Nekhoroshev estimates) is suggested by the data (5.5% periodicity at rank 9 vs. 0% at rank 7–8) but not proven. We state this as a conjecture: *configurations with high spectral rigidity (as measured by the fraction of eigenvalue-preserving perturbations) have higher probability of lying on or near invariant tori.*

The rank 7–8 fragility (2/100 spectrum-preserving) explains the apparent contradiction with earlier results that found 100% periodicity at these ranks in a targeted

search: those orbits exist but are measure-zero—any perturbation destroys the exact rank 7 structure and moves the system to rank 9 or higher.

A. Computational Efficiency

Computing the coupling tensor rank at a configuration requires one Hessian evaluation ($O(N^2)$ for the analytical Hessian) and one SVD ($O(N^3)$ for the 12×12 matrix). For our 3.24 million configuration landscape, this took 68 seconds on 48 CPU cores. By comparison, determining periodicity by integration required 8×10^4 leapfrog steps per orbit; 100,000 orbits took 280 seconds on a single GPU. The tensor rank computation is 97× faster per configuration than integration, making it practical as a screening tool for large-scale orbit surveys.

VI. CONCLUSION

The coupling tensor of the three-body problem at rank-9 configurations has exact Keplerian eigenvalue structure (2:1:1:0:0:0), which we prove implies spectral rigidity via the Davis-Kahan theorem. GPU integration of 100,000 orbits confirms that these spectrally rigid configurations have the highest periodicity rate. A machine learning classifier achieves $F_1 = 0.86$ for periodicity prediction from tensor features alone, 97× faster than direct integration.

The multilinear rank of the coupling tensor provides a computationally efficient, physically interpretable proxy for dynamical tractability in the three-body problem. Whether this framework extends to $N > 3$ bodies and to other coupled dynamical systems is an open question.
